[Abstract] Skyrmions are particle-like topological entities in a continuous field that have an important role in various condensed matter systems, including two-dimensional electron gases exhibiting the quantum Hall effect, chiral ferromagnets, and Bose-Einstein condensates. Here we show theoretically, with the aid of numerical methods, that a highly chiral nematic liquid crystal can accommodate a quasi two-dimensional Skyrmion lattice as a thermodynamically stable state, when it is confined to a thin film between two parallel surfaces imposing normal alignment. A chiral nematic liquid crystal film can thus serve as a model Skyrmion system allowing direct investigation of their structural properties by a variety of optical techniques at room temperatures that are less demanding than Skyrmion systems discussed previously.
[Introduction] Skyrme showed that particle-like topological excitations can be stable in certain types of continuous non-linear fields, and can account for the existence of protons and neutrons in the field of pions \(^1\). When one considers a continuous vector field \(m\) in three dimensions of fixed magnitude (i.e., \(m \in S^2\)), a Skyrmion is roughly understood to be a localized variation in the field, in which \(m\) rotates continuously through an angle \(\pi\) or \(\pi/2\) (in the case of a half Skyrmion) from its center to its boundary. Figure 1a illustrates the vector field profile of a half-Skyrmion.

Though the original idea of Skyrme was applied to a continuous field of pions to explain the existence of protons and neutrons\(^1\) as mentioned above, Skyrmions have found a place in a wide variety of fields of physics, in particular in condensed matter systems. In the mid-1990s Skyrmions were predicted and observed in quantum Hall devices \(^2,3,4\), with the realization that quantum effects are best understood in terms of topological features. Later, spinor Bose-Einstein condensates were shown to accommodate Skyrmions due to the internal spin degrees of freedom\(^5,6,7\). More recently, great attention has been paid to Skyrmions in helical ferromagnets \(^8\) such as MnSi \(^4,9,10\) and \(\text{Fe}_{1-x}\text{Co}_x\text{Si}\) \(^11,12\) characterized by a lack of inversion symmetry (chirality) and the presence of Dzyalonshinskii-Moriya spin-orbit interaction. Skyrmions in chiral ferromagnets could stimulate potential applications, because local twisted magnetic structures coupled to electric or spin currents could be used to manipulate electrons and their spins.

Among the intriguing features of helical ferromagnets is their similarity\(^9,13,14\) to cholesteric blue phases (BPs) in chiral liquid crystals\(^15\). BPs have attracted much interest as one of the fascinating non-trivial structures in condensed matter systems, where the unit vector \(n\), known as the director that denotes the average orientation of liquid crystal molecules, exhibits three-dimensional ordering. The delicate balance between the local preference for a double-twist structure over a single-twist in a helical
phase and the global topological constraint that prevents a double-twist structure from filling the whole space without introducing discontinuities yields three-dimensional regular stacks of so-called double-twist cylinders\(^{15}\) (Fig. 1b) and topological defect lines\(^{15}\). In Figs. 1c and d, we show the structures of bulk BPs with cubic symmetry. BP I in Fig. 1c is characterized by a space group \(O^8\) (I4\_32), and contains straight defect lines that do not intersect each other. Defect lines in BP II (Fig. 1d, space group \(O^2\), or \(P4_232\)) form a double-diamond structure with an array of four-arm junctions. Double-twist cylinders can be regarded as a type of Skyrmion excitation with \(\pi/4\) rotation. A \(\pi/4\) rotation enables the \(n\) field to remain continuous at the point of contact between two neighbouring orthogonal double-twist cylinders. Possibly due to the delicate balance mentioned above, most liquid crystals exhibiting a BP have a limited stability range in temperature as small as a few Kelvin or less. However, recently discovered polymer-stabilized BPs allow a temperature range wider than 60K\(^{16}\), which has stimulated numerous experimental studies aimed at practical applications of BPs such as fast-switching displays. Close similarity is apparent in the free energy densities, which take the form of \(a \cdot (\nabla \times a)\) that is allowed in the absence of inversion symmetry\(^{8,15}\), where \(a=n\) (director) in the case of liquid crystals and \(a=m\) (magnetization) in the case of ferromagnets. Possible ferromagnetic structures consisting of stacks of double-twist cylinders have also been discussed\(^{9,14}\).

Here we show theoretically, with the aid of numerical calculations, that a highly chiral liquid crystal can be host to a stable quasi-two-dimensional Skyrmion lattice when it is confined to a thin film between two parallel plates imposing normal alignment (anchoring) at the surfaces. It should be stressed that liquid crystals possess head-tail symmetry, thus \(n\) is equivalent to \(-n\), therefore, in comparison to magnets, they allow for a wider variety of ordered structures. Our present study is motivated by our discovery of a wide variety of ordered structures in a confined chiral liquid crystal\(^{17,18}\), and a very recent real-space observation of regular Skyrmion lattices in a
thin film of Fe_{1-x}Co_xSi\textsuperscript{12}. With the aid of extensive numerical calculations, we construct a phase diagram in terms of temperature and film thickness, and demonstrate that regular quasi-two-dimensional Skyrmion lattices with hexagonal or rectangular symmetry are indeed thermodynamically stable over a certain range of temperatures and film thicknesses.

**[Results] [Skyrmion structures]** Calculations are carried out in the temperature range \(-1.05\text{K} \leq T - T^* \leq 0.32\text{K}\), and the film thickness range \(50\text{ nm} \leq d \leq 200\text{ nm}\). Here \(T^*\) is the temperature below which an isotropic phase becomes unstable to any small perturbations. Details of our calculations are described in Methods. We present several thermodynamically stable profiles in our calculations in Figs. 2a-f. Here the director (\(n\)) profile at \(z=d/2\) (midplane of the system) and topological defects are depicted. Confining surfaces with strong normal anchoring no longer allow straight defect lines to exist, in contrast to bulk BPs, thus yielding various exotic ordered structures not found in bulk liquid crystals. In our previous study at a fixed temperature\textsuperscript{17,18}, we reported the observation of an array of double helix defect lines (Fig. 2e), or inchworm-like fragmented defects (Fig. 2f). By varying the temperature, we find a much wider variety of ordered structures as shown in Figs. 2a-d. Particularly interesting are those with hexagonal symmetry (Figs. 2a,b). In the case of small \(d\) (Fig. 2a), a two-dimensional (2D) lattice of half-Skyrmion excitations (Fig. 1a) embedded in an array of straight topological defect lines is clearly observed, resembling those found in a recent real-space observation of thin chiral ferromagnets\textsuperscript{12}. With increasing \(d\), variation of the profile in the \(z\) direction is allowed, which results in further exotic structures (Figs. 2b-d). The profile in Fig. 2c can also be regarded as a Skyrmion lattice because half-Skyrmion excitations are still clearly visible as a centered-rectangular lattice in an array of topological defects. In Fig. 2b, a labyrinth of topological defects with hexagonal symmetry prevents the formation of Skyrmion excitations. Though possible similar hexagonal structures in chiral liquid crystals have been discussed
Before\textsuperscript{19,20,21,22}, they are bulk structures (without confinement) under an electric field; the difference between the local nature of the surface anchoring and the long-range nature of the electric field should be stressed. Moreover, the confinement does not allow screw axes to arise\textsuperscript{17}, which are required for some observed and proposed bulk hexagonal structures\textsuperscript{19,20,21,22}. Indeed, structures seen in Figs. 2b and f cannot exist as bulk ones. It is interesting to note that in Fig. 2d, four-arm junctions of topological defects can be seen clearly, reminiscent of those in BP II (Fig. 1d). Here, and also in Figs. 2e and f, half-Skyrmion excitations forming a rectangular lattice can be observed. Typical lattice constants are 113nm for the hexagonal structure of Fig. 2a, and 91nm×101nm for the centered-rectangular structure of Fig. 2d. The dependence of the lattice constant on the temperature and film thickness is not strong; in the case of Fig. 2a, the lattice constant ranges from 106nm to 120nm. Smaller film thicknesses and lower temperatures yield a larger lattice constant.

**Phase diagram** In Fig. 2g, we present the phase diagram with respect to temperature $T$ and film thickness $d$. For higher temperatures, i.e., $T-T^* > 0.25$K, an alignment normal to the confining surfaces with reduced ordering in the middle of the system is the most stable state (we will refer to this state as NA or “normal alignment”). Note that the orientational order in the NA state is induced by confining surfaces\textsuperscript{23}; the temperature is too high to allow orientational order in the bulk. In the case of a lower temperature or small $d$, a helical orientational order corresponding to a cholesteric phase, whose pitch is parallel to the confining surfaces, attains thermodynamic stability (often referred to as “uniform lying helix (ULH)”). In between the normal alignment state and ULH, structures presented in Figs. 2a-f can be thermodynamically stable. For smaller $d$, a 2D hexagonal Skyrmion lattice (Fig. 2a) is energetically preferable. For larger $d$, thermodynamic stability of hexagonal structures (Fig. 2b) and rectangular structures (Fig. 2d,e) depends on temperature; the former is more stable for higher temperatures.
The stable regions for centered-rectangular structures (Fig. 2c) and for fragmented defects (Fig. 2f) are limited in extent.

**[Discussion]** Here we discuss the similarities and differences between the 2D hexagonal Skyrmion lattice in Fig. 2a, and the square one in Ref. 8. In both systems, half-Skyrmion excitations are embedded in a regular lattice of topological defects. The vectorial nature of the magnetization in the latter allows only Skyrmions with $+z$ magnetization to neighbour ones with $-z$ magnetization; otherwise the boundary between two Skyrmions must be discontinuous. Therefore, a hexagonal lattice is prohibited because it would lead to frustrations. For a hexagonal Skyrmion lattice to exist, Skyrmions with $+z$ magnetization must adopt a rotation of $\mathbf{m}$ in the sea of $-z$ magnetization$^{10,12}$. On the other hand, in liquid crystalline systems with $\mathbf{n}$ and $-\mathbf{n}$ symmetry, such frustrations do not exist, which allows for the formation of a hexagonal lattice of half-Skyrmions.

From the phase diagram presented in Fig. 2g, it is clear that if one wishes to observe 2D hexagonal Skyrmion lattices, the temperature must be carefully controlled within a range of 0.5K at most, just as BPs in the bulk are in most cases stable over a 1K temperature range$^{15}$. The stable temperature range of rectangular Skyrmion lattices is relatively large, compared to hexagonal lattices.

We find from a separate calculation that the thermodynamic stability of 2D hexagonal Skyrmion lattices is significantly reduced when the chirality of the liquid crystal is lower (larger cholesteric pitch). This observation corresponds to the well-known fact that cholesteric blue phases can be found only in highly chiral liquid crystals$^{15}$. Notice also that with weak surface anchoring, a structure similar to a bulk blue phase is the most stable$^{17}$, because the surfaces disturb little the bulk structure. Together with the phase diagram in Fig. 2g, we conclude that for the observation of 2D
Skyrmion lattices in a chiral nematic liquid crystalline system, the following conditions must be fulfilled: (1) high chirality, (2) accurate temperature control (close to the transition towards the isotropic phase), and (3) very small film thickness with strong surface anchoring.

Finally we comment on the possibility of observing the structures discussed here experimentally. The transition from a rectangular to a hexagonal structure induced by a temperature change would be clearly detected by scattering experiments. Transmission electron microscopy with a freeze fracture technique could help identify the orientational profile of a confined liquid crystal together with its spatial symmetry. A more recent and promising technique that allows real-space observation is confocal microscopy, which has been applied to observe a bulk blue phase, and defect structures in simple nematics and cholesterics. We note that liquid crystals have been exploited for modelling physical systems that are difficult to access experimentally and in which topology plays a substantial role. Experimental observation of liquid crystalline Skyrmion systems could also shed light on the properties of other experimentally demanding Skyrmion systems, for example, two-dimensional electron gases exhibiting quantum Hall effect, spinor Bose-Einstein condensates, and chiral ferromagnets, and clarify the similarities and differences between these systems. We thus encourage experimental studies for the observation of Skyrmion lattices in a liquid crystal. Further theoretical studies may be devoted to several interesting but challenging problems on, say, the dynamics of phase transitions induced by temperature change, and possible effects of thermal fluctuations on the stability of Skyrmion structures. We further note that photopolymerization, which was applied to the stabilization of BPs, could open a route to various Skyrmion structures stable over a wide temperature range. The Skyrmion structures could be templates for assembling complex structures of colloidal particles that can be further stabilized by photopolymerization for possible photonic applications.
[Methods] [Order parameter and the Landau-de Gennes theory] Our calculations are based on a Landau-de Gennes theory describing the orientational order in terms of a symmetric and traceless tensor $Q_{ij}$, with $i$ and $j$ representing the Cartesian coordinates $x, y, z$. When the liquid crystal is in an isotropic state, $Q_{ij}$ = 0. In the case of uniaxial ordering, $Q_{ij} = Q(n_i n_j - (1/3)\delta_{ij})$, where $Q$ describes the degree of orientational order, and $n_i$ is the $i$-th component of the director. The local free energy density in the bulk $f_{\text{local}}$, and the elastic energy $f_{\text{el}}$ are written as expansions in $Q_{ij}$ and its gradients, up to the lowest relevant order, as\(^{(1)}\):

$$f_{\text{local}} = c(T - T^*)Q_{ij}Q_{ij} - \sqrt{6}bQ_{ij}Q_{jk}Q_{ki} + a(Q_{ij}Q_{ij})^2$$

$$f_{\text{el}} = \frac{1}{4}K_1[\epsilon_{ikl}\partial_kQ_{lj} + 2q_0Q_{ij}]^2 + \frac{1}{4}K_0[\partial_jQ_{ij}]^2$$

Here summations over repeated indices are implied, and $a, b, c$ are material parameters assumed to be positive. Below the temperature $T^*$, an isotropic state becomes unstable with respect to small perturbations. $\epsilon_{ikl}$ is the Levi-Civita symbol, $K_1$ and $K_0$ are elastic constants, and $2\pi/|q_0|$ is the pitch of the cholesteric helix. For the free energy density of the confining surfaces, which we assume impose normal alignment (anchoring), we employ the following quadratic form\(^{(2)}\):

$$f_s = \frac{1}{2}W(Q - Q_s)_{ij}^2$$

where $W$ is the anchoring strength, and $(Q_s)_{ij} = Q_0(\nu_i \nu_j - (1/3)\delta_{ij})$ is the order parameter preferred by the surface, with $\nu$ being the surface normal vector and $Q_0$ being the degree of surface order. In the present study $Q_0$ is chosen such that $(Q_s)_{ij}$ minimizes $f_{\text{local}}$ for $T=T^*$.

[Calculation of the orientation profile] We consider a thin film of a liquid crystal confined by two parallel flat surfaces separated by a distance $d$. When we take
the $z$ axis normal to the surfaces, the total free energy $F$ is given by

$$F = \int dx \, dy \left[ \int_0^d dz \left( f_{\text{local}} + f_{\text{el}} \right) + f_s \right].$$

To obtain the orientational order profile minimizing $F$ numerically, we relax not only the order parameter $Q_{ij}$ but also the shape and size of the numerical system (imposing periodic boundary conditions in the $xy$ plane), using the procedures described in Refs. 17, 18 and 30. We choose typical material parameters\textsuperscript{18}

$a=8.0 \times 10^4$ J m$^{-3}$, $b=5.0 \times 10^4$ J m$^{-3}$, $c=3.0 \times 10^4$ J m$^{-3}$ K$^{-1}$, $K_1=K_0=10$ pN. We set the rescaled strength of chirality $\kappa \equiv \sqrt{a K_1 q_0^2 / b^2}$ to 0.7, and the rescaled anchoring strength $w = 2q_0 (a/b^2) W$ to 2.5, corresponding to choosing $2\pi/|q_0| \cong 161$ nm (cholesteric pitch), and $W \cong 1.0 \times 10^{-3}$ J m$^{-2}$ (anchoring strength). Thus we are considering high chirality and strong surface anchoring, but these values are experimentally achievable, and are expected to maximize frustrations that will give rise to a rich variety of exotic ordered structures.
